Abstract

We present a study of the whole sample of the Herbig Ae/Be stars observed with the spectrometers on board of the Infrared Space Observatory (ISO/ESA). These objects have been studied not only by means of their infrared continuum emission but also with respect to all the available photometric data, collected from the optical region to the radio wavelengths. The global spectral energy distributions (SEDs) have been compared with the results of radiative transfer calculations, that have been made in the framework of a circumstellar (CS) model. The results of the selection of the best models allow us to infer on the relationship between the geometry of the CS matter distribution and the evolutionary stage of these objects. KEYWORDS: stars: pre-main sequence – circumstellar matter – infrared: stars

1. Observations, data reduction and results

The ISO data archive has been searched for Short Wavelength Spectrometer (SWS) and Long Wavelength Spectrometer (LWS) observations related to Herbig AeBe stars (HAEBe stars hereinafter). We found 36 objects (out of 108 stars recognized in Thé et al. (1994)), which are listed in Table 1.

The SWS spectra we discuss here were taken in the range 2.3–45 μm with low resolution (λ/Δλ ~ 250) and a typical field of view increasing with wavelength from 14′′ × 20′′ to 20′′ × 33′′ (De Graauw et al., 1996), while the LWS spectra were obtained in the range 43–196.7 μm, λ/Δλ ~ 200, (Clegg et al., 1996). In the LWS spectral range the instrumental beam size is ~ 80′′ so that in some cases (12 objects) the observations were carried out also at an off-source position to account for the contamination due to the local background.

The raw SWS and LWS data were processed using version 10 of the off-line pipeline, which produced series of repeated spectral scans, each composed of 12 and 10 subspectra for SWS and LWS, respectively. These correspond to different spectral ranges, that are arranged to be partially overlapping. The data were further reduced and analysed in subsequent steps:

- removing bad points (glitches, residual detectors responsivity drifts);
- averaging of the many scans obtained on each subspectrum;
- removing of the low-frequency fringes, whose presence affects particularly the LWS spectra (Swinyard et al., 1998);
- smoothing of averaged spectra (SWS only).

Whenever possible, the off-source LWS spectra were subtracted from the corresponding on-source data. Notwithstanding accurate data reduction, the subspectra obtained appear in many cases not perfectly overlapping together, probably because of the variation of the beam size with the wavelength (De Graauw et al., 1996; Swinyard et al., 1998). In Fig. 1, we show examples of two reduced source spectra.

![Figure 1: ISO spectra. Both sources show a good continuity between SWS and LWS fluxes despite the different beam sizes involved. On the other hand they clearly present discontinuities in the LWS respective subspectra.](image-url)
2. Model calculation and comparison with observations

The SEDs emerging from CS envelopes have been computed by means of a model based on a spherical geometry of the circumstellar environment. The model is characterized by a density distribution $n(r)$ around a central star and by the presence of an HII region whose radius is determined by the ionizing luminosity of the central star. A temperature profile $T(r)$ is also considered for the dust component while for the gas we assumed $T = 10^4$ K in the HII region. The gas emission processes considered in the radiation transfer are: free-free, free-bound and electron scattering, while for the dust component the emissivity is computed on the basis of the “astronomical silicate” defined by Draine & Lee (1984). Cases with a modified dust emissivity (at $\lambda > 20\mu$m) have also been computed to take into account the fact that in star forming regions the average dust grain size can be larger than in the diffuse IS medium and consequently the opacity can be described by a $k \propto \lambda^{-\beta}$ law; in our case, $\beta = 1.2, 0.8, 0.6$ (see Pezzuto et al. (1997) for a more complete model description). In addition we also consider:

1) the possible presence of cavities in the CS envelope as can be evacuated by the strong stellar wind associated with the PMS phases;
2) the possibility of two different density distributions describing the inner
and outer parts of the envelope, respectively.

A large set of synthetic spectra has been computed; for each object we searched
for the best fit with the observed fluxes. Such a comparison, made by means of a
"chi square like" method, allows the selection of the best models for each object.
In doing this we considered not only the spectral fit but also the consistency of
the model fluxes with the spectral type estimated for the star, the distance, and
the observed visual absorption. An example of the results obtained is presented
in Table 2, and shown in Figure 1..
